(Received 13 April 1999; accepted 13 May 1999)

The weakly bound  $\text{Ca}(4s4d\sigma^3D_3) \cdot \text{Ar}[^3\Sigma^+]$  state has been characterized by means of R2PI (Resonant Two-Photon Ionization) spectroscopy, using transitions from the  $\text{Ca}(4s4p\pi^3P_0) \cdot \text{Ar}[^3\Pi_{0-}]$  metastable state prepared in a laser-vaporization/supersonic jet source. Because several of the vibrational levels are above the dissociation limit [to  $\text{Ca}(4s4d^3D_3) + \text{Ar}(^1S_0)$ ], it is concluded that there must be a substantial maximum in the  $\text{Ca}(4s4d\sigma^3D_3) \cdot \text{Ar}[^3\Sigma^+]$  potential curve ( $>200 \text{ cm}^{-1}$ ) at large  $R$  ( $>4.0 \text{ \AA}$ ). This is discussed, and shown to be consistent with our earlier ideas of “penetration” of outerlobes of electron density of metal atom excited states by RG (rare-gas) atoms. Perturbations observed, due to possible potential curve crossings with states of different electronic symmetry, are also discussed. © 1999 American Institute of Physics. [S0021-9606(99)00730-8]

## INTRODUCTION

Duval *et al.* experimentally characterized<sup>1</sup> the first case of a long-range potential curve maximum in a  $M^* \cdot \text{RG}$  excited state ( $M^*$ =electronically excited metal atom,  $\text{RG}$ =rare-gas atom) which was not due to an adiabatic avoided potential-curve crossing, when they showed, by means of careful laser double-resonance experiments, that the  $\text{Hg}(6s7s^3S_1) \cdot \text{Ar}[^3\Sigma^+]$  excited Rydberg state had a small ( $\sim 15 \text{ cm}^{-1}$ ) maximum in its potential curve at large  $R$  ( $\sim 5 \text{ \AA}$ ). They argued<sup>1</sup> that the maximum was at much too large a value of  $R$  to result from a curve crossing with the only other lower-lying  $\text{HgAr}(^3\Sigma^+)$  state, and postulated that the maximum was due to exchange repulsion of the Ar atom electrons with the outerlobe electron density of the  $\text{Hg}(7s)$  Rydberg electron.<sup>1,2</sup> At shorter internuclear distances  $R$ , Breckenridge *et al.* postulated<sup>1,2</sup> that the Ar atom had substantially “penetrated” the diffuse  $\text{Hg}(7s)$  electron cloud, and thus experienced strong attractive forces somewhat akin to those in the  $\text{Hg}^+(6s) \cdot \text{Ar}$  free ion [which has  $R_e, D_e$  values very similar to those of the  $\text{Hg}(6s7s^3S_1) \cdot \text{Ar}[^3\Sigma^+]$  Rydberg state]. Since then, several examples of these kinds of potential-curve maxima have either been demonstrated directly, or inferred, by our group as well as by others.<sup>3–13</sup> Theoretical *ab initio* calculations have also shown<sup>10,14–16</sup> such maxima, in cases where avoided curve crossings are quite unlikely, confirming the original “penetration” hypothesis<sup>1,2</sup> of Breckenridge *et al.* for such Rydberg states.

For  $M^*(np\sigma) \cdot \text{RG}$  or  $M^*(nd\sigma) \cdot \text{RG}$  excited states, the  $M^*$  outer electron density is more concentrated along the

bond axis as the RG atom approaches than for  $M^*(ns) \cdot \text{RG}$  states, where the  $M^*(ns)$  electron density is uniformly distributed (angularly), so that larger potential maxima might well be expected. We report here an experimental spectroscopic characterization of the excited  $\text{Ca}(4s4d\sigma^3D_3) \cdot \text{Ar}[^3\Sigma^+]$  state (formally “valence” in character) which shows that there must be a long-range maximum in the potential curve of at least  $200 \text{ cm}^{-1}$  at  $R > 4.0 \text{ \AA}$ , and that the actual bond strength ( $D_0$ ) is only  $134 \pm 50 \text{ cm}^{-1}$ . The bonding, as well as small perturbations apparently due to potential-curve crossings of states of other electronic symmetries, is discussed.

## II. EXPERIMENT

These experiments were carried out using an apparatus constructed for the spectroscopy of, and dynamics within, atom-(RG)<sub>n</sub>, and atom-(molecule)<sub>n</sub> van der Waals complexes using either laser-induced fluorescence (LIF) or resonance two-photon ionization (R2PI) detection. The apparatus is described in more detail elsewhere.<sup>17–19</sup>

Briefly, calcium vapor was produced by focusing the second harmonic of a Moletron MY-32/10 Q-switched Nd:YAG laser onto a calcium target rod (1/4 in. diam machined from Alpha/Aesar 99% pure ingot). An 800  $\mu\text{s}$  pulse of gas produced by a double-solenoid pulsed valve operated at 40 psi Ar backing pressure passed over the calcium rod coincident with the vaporization laser pulse. The Ca vapor/argon pulse then passed through a 1.8 mm orifice after having traveled 4 mm from the site of vaporization into the chamber maintained at  $6 \times 10^{-4}$  Torr. The beam, after passing through a 5 mm diam skimmer 20 cm from the source, entered the ionization region of a time-of-flight mass spectrometer at a total distance of 60 cm from the source. R2PI spectra are obtained by scanning the output of a dye laser to

excite transitions from the  $\text{Ca}(4s4p\pi^3P_J) \cdot \text{RG}(\ ^3\Pi_{0^-}, v''=0, J'')$  metastable states. Photoionization with a simultaneously pumped ionization dye laser created ions which were detected after a 1 m free-flight region. Dyes used: Coumarin 480 (resonance), Coumarin 500 (ionization).

### III. RESULTS AND DISCUSSION

#### A. Assignment of the electronic symmetry and the asymptotic atomic states of the upper state

We recently reported<sup>20</sup> the spectroscopic characterization of the  $\text{Ca}(4s4d\pi^3D_J) \cdot \text{Ar}[\ ^3\Pi_{0^-} ]$ ,  $\text{Ca}(4s4d\delta^3D_1) \cdot \text{Ar}[\ ^3\Delta_1 ]$  states, and the unusually strongly bound doubly excited  $\text{Ca}(4p\pi 4p\pi^3P_J) \cdot \text{Ar}[\ ^3\Sigma^- ]$  state, by laser excitation of the  $\text{Ca}(4s4p\pi^3P_0) \cdot \text{Ar}[\ ^3\Pi_{0^-} ]$  metastable state in the 22 000–23 300  $\text{cm}^{-1}$  energy region. We now report the spectroscopic characterization of several bands of another vibrational progression in the 22 500–22 900  $\text{cm}^{-1}$  region (see Fig. 1) which originally puzzled us. The rotational structure of some of the bands is virtually identical to bands in the 15 800–16 400  $\text{cm}^{-1}$  region which we earlier successfully simulated<sup>13</sup> as  $\text{Ca}(4s5s^3S_1) \cdot \text{Ar}[\ ^3\Sigma^+ ] \leftarrow \text{Ca}(4s4p\pi^3P_0) \cdot \text{Ar}[\ ^3\Pi_{0^-} ]$  transitions. [The upper state in this case *must* be of  $\ ^3\Sigma^+$  symmetry, since the  $\text{Ca}(4s5s^3S_1)$  state is the only asymptotic triplet atomic state of Ca within 4000  $\text{cm}^{-1}$ .<sup>13</sup>] For example, shown in Fig. 2(a) is a high-resolution spectrum of the (5,0) band of the  $5s^3\Sigma^+$  transition<sup>13</sup> as compared to [Fig. 2(b)] a high-resolution spectrum of the band at 22 639.7  $\text{cm}^{-1}$  in the progression of Fig. 1.

Shown in Fig. 3 are the rotational branches expected for a  $\ ^3\Sigma^+(b) \leftarrow \ ^3\Pi_{0^+,0^-}(a)$  transition. Since only the lowest energy multiplet,  $\text{Ca}(4s4p\pi^3P_0) \cdot \text{Ar}[\ ^3\Pi_{0^-} ]$ , is known to be populated under our conditions,<sup>13</sup> there is one *S*-type branch spread out to the blue, three degenerate *Q*-type branches spread slightly to the blue of the band origin, and an *O*-type

FIG. 2. (a) High-resolution spectrum of the (5,0) band of the transition to the  $\text{Ca}(4s5s^3S_1) \cdot \text{Ar}[\ ^3\Sigma^+ ]$  state. (b) High-resolution spectrum of the band at 22 639.7  $\text{cm}^{-1}$  in Fig. 1. (The horizontal axis scale for the two spectra, in  $\text{cm}^{-1}$ , is the same.)

branch which heads to the red. All of the five bands in the progression in Fig. 1 which we have been able to simulate successfully have this same kind of structure, so we can clearly assign the electronic symmetry of the upper state in

FIG. 3. Schematic diagram showing the rotational branches for  $\ ^3\Sigma^+(b) \leftarrow \ ^3\Pi_{0^+,0^-}(a)$  transitions. Branch notation: Capital letter indicates the "form" of the branch,  $N' \leftarrow J'$ , while the small letter following indicates the  $J' \leftarrow J''$  character of the branch. For example, for an *Sr* branch  $N' = J'' + 2$ , and  $J' = J'' + 1$ .

the progression in Fig. 1 as  ${}^3\Sigma^+$ . (But see below for further discussion of two of these bands.) One of the problems with this assignment, however, is that a linear Birge–Sponer extrapolation of the bands yields an approximate dissociation limit [given the estimated  $D_0=60\pm 50\text{ cm}^{-1}$  of the  $\text{Ca}(4s4p\pi^3P_0)\cdot\text{Ar}[{}^3\Pi_{0-}]$  lower state]<sup>20</sup> which is nowhere near any asymptotic excited  $\text{Ca}^*$  state which can yield a  $\text{CaAr}[{}^3\Sigma^+]$  molecular state.

The Birge–Sponer extrapolated dissociation limit is  $38\,229\text{ cm}^{-1}$  [with  $E=0$  set as  $\text{Ca}(4s^21S_0)+\text{Ar}$ ]. The closest asymptotic states,<sup>21</sup>  $\text{Ca}(3d4p^3D_0^0)$  at  $38\,192\text{--}38\,259\text{ cm}^{-1}$ , can only produce  ${}^3\Sigma^-$ ,  ${}^3\Pi$ , and  ${}^3\Delta$  states when bound to Ar.<sup>22</sup> The  $\text{Ca}(4p^2^3P_J)$  states, at  $38\,418\text{--}38\,551\text{ cm}^{-1}$ , can also only yield  ${}^3\Sigma^-$  and  ${}^3\Pi$  states when bound to Ar.<sup>22</sup> The next highest states,  $\text{Ca}(3d4p^3P_0^0)$  at  $39\,333\text{--}39\,340\text{ cm}^{-1}$ , can yield  ${}^3\Sigma^+$  and  ${}^3\Pi$  states,<sup>22</sup> but this would require a huge bond energy for the observed  ${}^3\Sigma^+$  state of  $D_0\approx 1709\text{ cm}^{-1}$ . Not only is this very unlikely, since the wave function of this  ${}^3\Sigma^+$  state must have *some*  $3d\sigma 4p\sigma$  character which will be *extremely* repulsive in nature (in addition, of course, to attractive  $3d\pi_{+1}4p\pi_{-1}$  character) it would also require that the true dissociation energy be more than  $1100\text{ cm}^{-1}$  greater than the extrapolated linear Birge–Sponer value of  $\sim 605\text{ cm}^{-1}$ . Although true dissociation energies of these kinds of complexes are often slightly greater than the linear Birge–Sponer values due to the fact that a Morse potential function cannot correctly represent the dispersive attractive forces near dissociation, this is far outside such expected minor differences, and  $\text{Ca}(3d4p^3P_0^0)+\text{Ar}$  therefore cannot be the dissociation limit for this  ${}^3\Sigma^+$  state. The  $R_0$  value ( $3.31\text{ \AA}$ ) is also much too large for a state bound by  $\sim 1700\text{ cm}^{-1}$ ; the very strongly bound ‘‘pure- $\pi$ ’’  $\text{Ca}(4p\pi 4p\pi^3P_J)\cdot\text{Ar}[{}^3\Sigma^-]$  state ( $D_0=1278\text{ cm}^{-1}$ ) has an  $R_0$  value of  $<3.0\text{ \AA}$  (see below, and Fig. 8). Finally, the vibrational frequency,  $\sim 61\text{ cm}^{-1}$ , is about half that of the strongly bound  $\text{Ca}(4p\pi 4p\pi^3P_J)\cdot\text{Ar}[{}^3\Sigma^-]$  state,<sup>20</sup>  $\sim 118\text{ cm}^{-1}$ .

We are therefore forced to conclude that the only reasonable dissociation limit for this state is the lower-lying  $\text{Ca}(4s4d^3D_3)$  state, which yields a  ${}^3\Sigma^+$  state with  $\text{Ca}(4d\sigma)$  alignment with respect to the Ar atom. Because several of the observed vibrational levels are *above* the asymptotic energy of  $\text{Ca}(4s4d^3D_3)+\text{Ar}$ , the potential curve of the  $\text{Ca}(4s4d\sigma^3D_3)\cdot\text{Ar}[{}^3\Sigma^+]$  state must have a substantial *maximum* ( $>200\text{ cm}^{-1}$ ) at large internuclear distances ( $R>4.0\text{ \AA}$ ). This is actually quite a reasonable possibility, as we discuss below.

## B. Vibrational assignments

The moderately strong band at  $22\,525.7\text{ cm}^{-1}$  in Fig. 1 was assigned as the (0,0) band, since there was absolutely no sign of another band to the red at the energy expected from the band origin progression. (The signal-to-noise was too low for reliable  ${}^{40}\text{Ca}^{40}\text{Ar}/{}^{44}\text{Ca}^{40}\text{Ar}$  isotopic splitting measurements, since  ${}^{44}\text{Ca}$  has an isotopic abundance of only 2.1%; Ar is essentially monoisotopic.)

FIG. 4. High-resolution spectrum of the (0,0) band. Computer simulation is shown below. Simulation parameters:  $B'_0=0.0555\text{ cm}^{-1}$ ,  $B'_0=0.0761\text{ cm}^{-1}$ ,  $T=0.8^\circ\text{ K}$ , laser linewidth:  $0.09\text{ cm}^{-1}$ ,  $\lambda_{s,s}=-0.12\text{ cm}^{-1}$  (see text).

## C. Rotational analysis

Shown in Figs. 4–8 are high-resolution spectra of the  $(v',0)$  bands ( $v'=0\text{--}4$ ), along with the successful computer simulations of the band contours, assuming a  ${}^3\Sigma^+(b)\leftarrow{}^3\Pi_{0-}(a)$  transition, as discussed above. For the (1,0), (2,0), and (3,0) bands, the spin–spin splitting constant was successfully set to zero [as was the case with all the  $\text{Ca}(4s5s^3S_1)\cdot\text{Ar}[{}^3\Sigma^+]\leftarrow\text{Ca}(4s4p\pi^3P_0)\cdot\text{Ar}[{}^3\Pi_{0-}]$  transitions simulated earlier].<sup>13</sup> For the (0,0) and (4,0) bands, however, small spin–spin splitting constants of  $\lambda_{s,s}\approx -0.12\text{ cm}^{-1}$  were absolutely required to get a reasonable

FIG. 5. Same as Fig. 4, but (1,0) band.  $B'_1=0.0741\text{ cm}^{-1}$ ,  $\lambda_{s,s}=0.00\text{ cm}^{-1}$ .

FIG. 6. Same as Fig. 4, but (2,0) band.  $B'_2=0.0721\text{ cm}^{-1}$ ,  $\lambda_{\text{s.s.}}=0.00\text{ cm}^{-1}$ .

fit. “Spin–spin” splitting<sup>23,24</sup> causes the degenerate  $J$  levels of each  $N$  level to split, until at high values of  $\lambda_{\text{s.s.}}$  the  $^3\Sigma^+(b)$  state evolves into two case “c” type states ( $\Omega=0^-$  and  $\Omega=\pm 1$ ).<sup>23</sup> (For a heavy atom like Ca, true “spin–spin” coupling is very small, and the “spin–spin” splitting is actually due to second-order spin-orbit coupling.<sup>24</sup>)

The signal-to-noise of the (6,0) band was too low for rotational analysis, and we have also been unable to simulate satisfactorily the rotational structure of the (5,0) band assuming a simple  $^3\Sigma^+(b)\leftarrow^3\Pi_0^-(a)$  transition and either positive or negative  $\lambda_{\text{s.s.}}$  values up to several  $\text{cm}^{-1}$ . There is also

FIG. 7. Same as Fig. 4, but (3,0) band.  $B'_3=0.0698\text{ cm}^{-1}$ ,  $\lambda_{\text{s.s.}}=0.00\text{ cm}^{-1}$ .

FIG. 8. Same as Fig. 4, but (4,0) band.  $B'_4=0.0679\text{ cm}^{-1}$ ,  $\lambda_{\text{s.s.}}=-0.11\text{ cm}^{-1}$ .

an “extra” unassigned band  $\sim 3.5\text{ cm}^{-1}$  to the blue of the (5,0) band, which could also not be simulated satisfactorily. The (5,0) band thus appears to be severely perturbed, and we will discuss possible perturbing states later. The band origins, and  $B'_v$  values for the fit bands, are listed in Table I. The spectroscopic constants for the upper and lower states are listed in Table II.<sup>25</sup> The small  $D_o$  (and  $D_e$ ) values listed in Table II for the  $\text{Ca}(4s4d\sigma^3D_3)\cdot\text{Ar}[^3\Sigma^+]$  state are calculated via a thermochemical cycle:

$$D_o(^3\Sigma^+) = D_o(^3\Pi_0^-) + E(^3D_3) - E(^3P_0) - \nu_{0,0}$$

using an estimate<sup>20</sup> of  $D_o(^3\Pi_0^-) = 60 \pm 50\text{ cm}^{-1}$ .

#### D. Possible perturbations of the $\text{Ca}(4s4d\sigma^3D_3)\cdot\text{Ar}[^3\Sigma^+]$ levels by curve crossings

Shown in Fig. 9 are our estimates of the potential curves of the states in this energy region which have been characterized spectroscopically. The unusual, strongly bound  $\text{Ca}(4p\pi 4p\pi^3P_J)\cdot\text{Ar}[^3\Sigma^-]$  state is severely predissociated,<sup>20</sup> washing out all rotational structure, but  $D_e$  is accurately known. We estimated the  $R_e$  value for this  $^3\Sigma^-$  state by Franck–Condon simulations of the low-resolution

TABLE I. Band origins and  $B'_v$  values for the  $\text{Ca}(4s4d\sigma^3D_3)\cdot\text{Ar}[^3\Sigma^+]$  –  $\text{Ca}(4s4p\pi^3P_0)\cdot\text{Ar}[^3\Pi_0^-]$  transitions ( $B'_0=0.0555\text{ cm}^{-1}$ ). Values for (5,0) and (6,0) bands are from low-resolution spectra.

vibrational progression,<sup>20</sup> knowing  $R_o = 3.90$  Å for the  $\text{Ca}(4s4p\pi^3P_0) \cdot \text{Ar}[\text{}^3\Pi_{0-}]$  lower state.<sup>13</sup> Also shown in this figure are the  $\nu' = 0-6$  vibrational levels of the  $^3\Sigma^+$  state. Note that the  $^3\Sigma^-$  potential curve crosses the  $^3\Sigma^+$  potential curve near the  $^3\Sigma^+$  ( $\nu' = 0$ ) vibrational level.

The “ $\Omega = 0^+$ ” levels of a  $^3\Sigma^-$  state cannot interact with the “ $\Omega = 0^-$ ” levels of a  $^3\Sigma^+$  state because they have opposite parities (*e* versus *f*, respectively). However, the *e/f* pairs of  $\Omega = 1$  levels of a  $^3\Sigma^-$  state *can* interact with the *e/f*  $\Omega = 1$  pairs of levels of a  $^3\Sigma^+$  state.<sup>26</sup> If the  $^3\Sigma^-/{}^3\Sigma^+$  curve crossing is just above the  $\nu' = 0$  level of the  $^3\Sigma^+$  state, as indicated, this would push the  $\Omega = 1$  level of the  $^3\Sigma^+$  ( $\nu' = 0$ ) state *below* that of the  $\Omega = 0^-$  level, resulting in apparently *negative* values of  $\lambda_{\text{S,S}}$  for the  $\nu' = 0$  level, as observed. The interaction would be weak (as observed) since the  $\text{Ca}(4p\pi_{+1}4p\pi_{-1}) \cdot \text{Ar}[\text{}^3\Sigma^-]$  molecular orbital configuration is quite different from the  $\text{Ca}(4s\sigma_04d\sigma_0) \cdot \text{Ar}[\text{}^3\Sigma^+]$  configuration, so that the coupling is probably determined by how “mixed” these states are with other configurations.

FIG. 9. Plots of the potential curves of the relevant CaAr excited states which have been characterized experimentally. (See text.)

(Because of the similar energies of the  $3d$ ,  $4s$ , and  $4p$  orbitals in Ca, there are several low-lying doubly excited atomic states,<sup>21</sup> and thus many possibilities.)

However, the  $^3\Sigma^+/{}^3\Sigma^-$  crossing indicated in Fig. 9 cannot explain either the  $\lambda_{\text{S,S}} \approx -0.12 \text{ cm}^{-1}$  value for the  $\nu' = 4$  band nor the apparently strong perturbation of the  $\nu' = 5$  band. There will be another, fairly strongly bound  $^3\Sigma^-$  state from the  $\text{Ca}(3d4p^3D_1) + \text{Ar}$  asymptote, however (see Fig. 9): the “pure- $\pi$ ”  $\text{Ca}(3d\pi_{+1}4p\pi_{-1}^3P_0) \cdot \text{Ar}[\text{}^3\Sigma^-]$  state. Now, if this state is slightly *less* bound than the “pure- $\pi$ ”  $\text{Ca}(4p\pi_+4p\pi_-^3P_J) \cdot \text{Ar}[\text{}^3\Sigma^-]$  state [there should be more repulsion with the Ar atom for  $\text{Ca}(3d\pi)$  than for  $\text{Ca}(4p\pi)$ ], the potential curve for this state might cross that for the  $^3\Sigma^+$  state (shown in Fig. 9) *very* near the  $\nu' = 5$  level on the outer wing of the  $^3\Sigma^+$  potential curve. If so, this could possibly account for the severe perturbation of the  $\nu' = 5$  level as well as the negative  $\lambda_{\text{S,S}}$  value for the  $\nu' = 4$  level as well, if the interaction is stronger than for the  $\nu' = 0$  perturbation. We admit this is quite speculative, but it is at least plausible.

There are also several other possibilities of curve-crossing couplings from states which evolve from *lower-energy*  $\text{Ca}^* + \text{Ar}$  asymptotes:

### 1. $\text{Ca}(4s4d^1D_2) (E = 37\,298 \text{ cm}^{-1})$

Oddly, this singlet atomic state is actually slightly lower in energy than the triplet  $\text{Ca}(4s4d^3D_J)$  states because of mixing of higher-energy  $\text{Ca}(4p4p^1D_2)$  character into the nominally  $\text{Ca}(4s4d^1D_2)$  state, pushing it down in energy.<sup>21</sup> The molecular states possible are  $^1\Sigma_0^+$ ,  $^1\Pi_1$ , and  $^1\Delta_2$ . The  $^1\Pi$  state could interact specifically with the  $^3\Sigma_1^+$  components, but this state should be fairly strongly bound (with a potential curve similar to that of the  $4s4d^3\Pi$  state shown in Fig. 9), and thus should not cross the  $4s4d^3\Sigma^+$  potential curve. The  $^1\Sigma_0^+$  state (*e* parity) cannot interact directly with the  $^3\Sigma_0^-$  state (*f* parity), and the  $^1\Delta_2$  state  $\Omega = 2$  cannot interact with either of the  $\Omega = 0^-, 1$  components of the  $^3\Sigma^+$  state.

### 2. $\text{Ca}(4s5p^1P_1^o)$ and $\text{Ca}(4s5p^3P_2^o) (E = 36\,548-36\,732 \text{ cm}^{-1})$

The  $^1\Sigma^+$ ,  $^1\Pi$ ,  $^3\Sigma^+$ ,  $^3\Pi$  Rydberg type states from these asymptotes are probably all too bound to cross the  $^3\Sigma^+$  potential curve, and only the very bound  $^1\Pi_1$  state could interact appropriately in any case.

### 3. $\text{Ca}(3d4p^1D_2) (E = 35\,835 \text{ cm}^{-1})$

Of the  $^1\Sigma^-$ ,  $^1\Pi_1$ , and  $^1\Delta_2$  states possible here, the  $^1\Sigma_0^-$  state could interact specifically with the  $^3\Sigma_0^+$  component, and the  $^1\Pi_1$  state could interact specifically with the  $^3\Sigma_1^+$  components. However, the  $^1\Sigma^-$  state will have a unique  $3d\pi_{+1}4p\pi_{-1}$  type M.O. configuration, will thus be quite bound, and should not cross the higher-lying  $4s4d^3\Sigma^+$  potential curve. But the  $^1\Pi_1$  state has “mixed” ( $3d\delta_{+2}4p\pi_{-1} + 3d\sigma_+4p\pi + 3d\pi_+4p\sigma$ ) character, may be sufficiently repulsive to cross the higher  $^3\Sigma^+$  potential curve on its inner limb near the  $\nu' = 5$  level, and thus must be considered a possible perturbing state.

#### 4. $\text{Ca}(3d4p^3F^0)(E=35\,730\text{--}35\,897\text{ cm}^{-1})$

Of the possible  $^3\Sigma^+$ ,  $^3\Pi$ ,  $^3\Delta$ ,  $^3\Phi$  states, only the  $^3\Delta_1$  state could interact appropriately (with the  $4s4d^3\Sigma_1^+$  components). This state will also be of “mixed” ( $3d\delta 4p\sigma + 3d\pi_{+1}4p\pi_{+1}$ ) character, and so must also be under active suspicion as a possible perturbing state, because it may also be quite repulsive in nature.

#### E. Van der Waals bonding in the $\text{Ca}(4s4d\sigma^3D_3) \cdot \text{Ar}[^3\Sigma^+]$ state

We believe that the Ar atom can penetrate the diffuse  $\text{Ca}(4d\sigma)$  “valence” orbital ( $4d_{z^2}$ ), even along the bond axis where there is a concentration of electron density, because the  $\text{Ca}(4d)$  orbital is quite diffuse and also has a radial node. As the Ar atom enters the radial node region, the electron–electron repulsion will drop precipitously, resulting in a slight net attraction at  $R_o = 3.31 \text{ \AA}$ . No such attractive  $^3\Sigma^+$  state has been observed<sup>17</sup> for the analogous “valence”  $\text{Mg}(3s3d\sigma^3D) \cdot \text{Ar}[^3\Sigma^+]$  state [where the  $\text{Mg}(3d)$  orbital is also highly excited and quite diffuse], since there is no “node” in the  $\text{Mg}(3d\sigma)$  orbital, and the interaction is therefore purely repulsive at moderate  $R$ . On the other hand, the highly excited Rydberg  $\text{Mg}(3s4d\sigma^3D_3) \cdot \text{Ar}[^3\Sigma^+]$  state has been characterized,<sup>27</sup> and was shown to be fairly strongly bound,  $D_o = 800 \pm 40 \text{ cm}^{-1}$ , presumably due to both the very diffuse nature of the  $\text{Mg}(4d)$  Rydberg orbital as well as the presence of the  $\text{Mg}(4d)$  radial node. The  $\text{Mg}(3s4d\pi^3\Pi)$  and  $\text{Mg}(3s4d\delta^3\Delta)$  Rydberg states<sup>27</sup> have larger  $D_o$  values of  $1230 \pm 50 \text{ cm}^{-1}$  and  $1200 \pm 40 \text{ cm}^{-1}$ , respectively, as expected, very similar to the  $D_e$  value for the  $\text{Mg}^+(3s) \cdot \text{Ar}[^2\Sigma^+]$  “core” ion,  $1240 \pm 40 \text{ cm}^{-1}$ , since the Ar atom can approach along *angular* nodal axes.

States with potential curve maxima at large  $R$ , where  $v'$  levels can exist quite happily far above the dissociation limits to the atomic asymptotic products, have been observed directly by others. For example, Tsuchiya *et al.*<sup>3</sup> have characterized the  $\text{Hg}(6s7s^3S_1) \cdot \text{Ne}[^3\Sigma^+]$  state, where both the  $v' = 0, 1$  levels are above the  $\text{Hg}(6s7s^3S_1) + \text{Ne}$  asymptotic energy, and have shown *experimentally* that there is a maximum in the potential curve of  $\sim 150 \text{ cm}^{-1}$  at  $R = 4.0 \text{ \AA}$ .
