ABSTRACT: Heathland habitats in Ireland occur primarily in an oceanic setting which is strongly influenced by changes in the climate. Because of the oceanic environment, Ireland has a high proportion of the northern Atlantic wet heaths and alpine and boreal heaths of high conservation value within Europe. Future climate change is widely expected to place additional pressure on these systems. Seven bioclimatic envelope modelling techniques implemented in the BIOMOD modelling framework were used to model wet heath and alpine and boreal heath distributions in Ireland. The 1961–1990 baseline models closely matched the observed distribution and emphasise the strong dependency on climate. Mean winter precipitation, mean winter temperature and elevation were found to be important model components. The fitted model’s discrimination ability was assessed using the area under the curve; a receiver operating characteristic plot; the true skill statistic; and Cohen’s kappa. A BIOMOD ensemble prediction from all the models was used to project changes based on a climate change scenario for 2031–2060 dynamically downscaled from the Hadley Centre HadCM3-Q16 global climate model. The climate change projections for the individual models change markedly from the consistent baseline predictions. Although the consensus models project gains in climate space for both habitats in other parts of the country, new habitat formation in these areas is unlikely, as current (and hence near-future) land use and other conditions are not likely to favour expansion.

1. INTRODUCTION

1.1. Conservation importance of maritime uplands

Mountainous regions contain a high proportion of the world's biodiversity (Orme et al. 2005), including a range of species with unique adaptations and high extinction risk (Ricketts et al. 2005). Future climate change is widely thought to have the potential to exacerbate both the pace and the amplitude of these extinctions (Bellard et al. 2014). It is anticipated that an amplification of the elevation-dependent warming already detected will accelerate the rate of change in mountain ecosystems (Pepin et al. 2015). However, projections from different climate models vary markedly, and local processes for upland regions are poorly captured (Coll 2010, Coll et al. 2010); hence, more localised modelling studies are required to inform management decisions. The oceanic upland habitats of Ireland and Scotland and their associated oceanic species and vegetation are of high conservation value but are also considered vulnerable to climate change (Coll et al. 2010, 2014a, Hodd & Sheehy Skeffington 2011a). Heathlands are typically communities that flourish in oceanic climates both at altitudes above the tree line and at sea level (Crawford 2008). A fuller account of species assemblages for Irish montane heaths is provided in Hodd & Sheehy Skeffington (2011a), and a review of drivers of change for heaths in Fagúndez (2013). Heath communities have a restricted global distribution and support many species of limited distribution in Europe; consequently, Ireland has a special responsibility under the European Union (EU) Habitats Directive (Council Directive 92/43/EEC) to conserve them (Holden et al. 2007). This study focuses on 2 habitats listed in Annex I of the EU Habitats Directive, the 4010 northern Atlantic wet heaths and 4060 alpine and boreal heaths, as defined in the Habitats Interpretation Manual (EU 2013).

1.2. Bioclimatic envelope modelling

Various modelling approaches have been used to convert species distributions into predictive maps, and bioclimatic envelope models (BEMs) — which can be considered as a variant of niche-based or species distribution models (Guisan & Thuiller 2005, Heikkinen et al. 2006) — are widely used. However, confidence in the predictive power of BEMs is compromised by conceptual, biotic and algorithm flaws. These include unrealistic model assumptions (Schroder & Seppelt 2006, Dormann 2007), uncertainty regarding variable selection (Austin & Van Niel 2011), and lack of agreement over the classification of basic concepts (Segurado & Araújo 2004, Araújo & Guisan 2006, Austin 2007). Hence, there is ongoing debate concerning the strengths and limitations of the models and potential areas for their improvement (Araújo & Peterson 2012).

Arising from this debate, the use of consensus methods is popular on the basis that they decrease the predictive uncertainty of single models by combining their predictions (Marmion et al. 2009b, Grenouillet et al. 2011) and provide the advantage of combining forecasts to give a probability distribution per pixel as opposed to a single value (Thuiller 2014). Therefore, the ensemble prediction provided by the BIOMOD modelling framework (Thuiller 2003, Thuiller et al. 2009) is particularly useful in reducing the uncertainty associated with individual model types.

The use of BEMs for habitats is novel, and only a limited number of studies have applied these methods to landforms and habitats (e.g. Fronzek et al. 2006, Parviainen & Luoto 2007). However, based on work undertaken for UK (Clark et al. 2010) and Irish peatlands (Coll et al. 2011, 2013, 2016), climate is known to exert a strong control on these upland ecosystems and underpins the decision to apply BEMs to the heath habitats here.

1.3. 4010 northern Atlantic wet heaths

Northern Atlantic wet heaths in Ireland result from several thousands of years of a wet, oceanic climate that has resulted in the formation of shallow peat, even on montane slopes, often in a complex mosaic with blanket bog and dry heath. Historical grazing by stock in varying intensities and/or burning regimes are also contributing factors to plant community variation. The vegetation is typically dominated, to varying degrees, by a mix of *Calluna* heath, *Racomitrium* moss heath, grassland and blanket bog. Stands of wet heath occur on acidic, nutrient-poor substrates where rainfall maintains them in a permanently wet condition but where factors such as slope prevent deep peats from forming. Therefore, at all altitudes in a maritime setting, heath development is the result of interactions between a cool, wet, Atlantic climate and drainage extent.

The European distribution of wet heath is restricted to the areas of oceanic and on the periphery of the eastern North Atlantic region below the alpine zone. In Ireland and the UK, wet heath is usually found in the wetter climates of the north and west (Hampton 2008) and in eastern areas is restricted to uplands associated with higher rainfall. Here, the oceanic climate also results in a lower tree line than in more continental uplands (Crawford 2005). Habitat 4010 wet heath has been defined in an Irish context as a highly variable habitat, usually dominated by the graminoid *Molinia caerulea* or sedge (*Cyperaceae*) species, with a sparse cover of dwarf shrubs (Perrin et al. 2014). Intermediate in many regards between dry heath and blanket bog, the habitat generally occurs on gently sloping ground on shallow or intermediate (<1 m) peat depths (Perrin et al. 2014). The habitat is widespread in the west but is absent from large parts of the northern Midlands, as conditions are not suitable for wet heath (Fig 1a).

The dominant and characteristic plant species of wet heath are not considered sensitive to climate change (Berry et al. 2005) and may even benefit from the predicted milder, wetter winters and drier summers (Berry et al. 2002). However, many European heathland areas face an uncertain future due to a wide range of other pressures and drivers (Fagúndez 2013). The response to climate change will be determined by how shifts in precipitation, air temperature, humidity and wind speed affect seasonal and inter-annual soil moisture balances. Higher temperatures are expected to result in increased biomass production in heath communities providing that soil moisture changes do not lead to an increased drying of soils (Peñuelas et al. 2004).

Changes in relation to climate change are uncertain, but amid various contradictory interpretations, there are indications that wet heath will not be adversely affected and that an increase in annual rainfall totals may encourage the development of wet heath at the expense of dry heath (Hampton 2008). Warmer summers and wetter winters could also indirectly affect upland heaths through their impact on peat soils and the potential release of carbon locked up in these soils (Kirschbaum 2000).

Winter re-wetting may potentially exacerbate erosion and lead to a decline in the quality and extent of the habitat.

1.4. 4060 alpine and boreal heaths

Alpine and boreal heath habitats are found in mountain areas across Europe and, in continental mountain ranges, are usually located between the tree line and the grassland communities. Associated with shallow mineral soils, the heaths are also found on areas of loose rock and coarse sediment on mountaintops and ridges (Zaghi 2008). Alpine heaths develop above the natural altitudinal tree line, whereas boreal heaths develop below the tree line in gaps among scrubby high-altitude woodland, although this distinction is not clear in oceanic areas (Hodd & Sheehy Skeffington 2011a).

The habitat in Ireland is one where vegetation cover is rarely complete but normally exceeds 50% (Fossitt 2000). Alpine and boreal heath in good condition is typically dominated by a range of low-growing, wind-clipped dwarf shrubs, but in oceanic areas, dwarf shrub cover is often low, with the moss *Racomitrium lanuginosum* becoming dominant (Hodd & Sheehy Skeffington 2011a, Perrin et al. 2014). Irish alpine and boreal heath is confined largely to the mountain areas, with a limited distribution in Northern Ireland (Fig. 1b). Alpine and boreal heath has been highlighted as sensitive to a changing climate (Zaghi 2008), and climate change is projected to adversely affect arctic–montane plants in Ireland generally (Coll et al. 2013, Hodd et al. 2014).

Re-survey data in the Scottish Highlands show that a loss of specialised species has already taken place in some dwarf shrub heaths, grasslands and alpine heaths (Ross et al. 2012, Ross 2015). Model-based results from Scotland also indicate major shifts in seasonal isotherms associated with upland zones (Coll 2007, Coll et al. 2010). However, while some tree encroachment into the sub-alpine zone is possible, this is unlikely to occur since tree lines in Ireland are significantly affected by wind (Hodd & Sheehy Skeffington 2011a). Thus, the interaction between local topography and possible wind field changes is likely to remain a more significant local control for Ireland, while future management regimes, particularly grazing levels, will also be important.

Although suitable climatic conditions are likely to persist for some heath types in Ireland, details of the effects of a changing climate on distributions are currently unclear. Any climatic change will be exacerbated on the mountain summits and on habitats currently at the edge of their natural range (Coll et al. 2010). It is likely that more sensitive species will be more vulnerable (Coll et al. 2013) and that the small area and low altitude of Ireland's mountains reduce species' options to track areas of suitable climate (Hodd et al. 2014).

The primary aim of this study was to model the impacts of climate change for wet heath and alpine and boreal heath Annex I habitats for the island of Ireland using climate and elevation variables as predictors in a BEM framework. In addition, a consensus model based on the averaged spatial probabilities for the model categories selected was used to project changes in future climate space for both habitat types. Insofar as we are aware, this is the first application of a BEM ensemble modelling framework to heathland habitat data, and the approach with some refinements could be used to inform future management.

2. MATERIALS AND METHODS

2.1. Study area

The study area is the whole island of Ireland and covers ca. 84421 km² on the Atlantic margin of northwestern Europe, between the latitudes of ca. 51° 00' and 56° 00' N (Fig. 1a). Altitudes range up to 1040 m a.s.l. (Corrán Tuathail, County Kerry). Much of the island is lowland, with mountain areas mainly being near the coast and with a characteristic temperate oceanic climate. Mean annual temperature (averaged over 1961–1990) is highest on the southwestern coast (10.4°C) and lowest inland (8.8°C). On average, annual precipitation ranges from 750 to 1000 mm yr⁻¹ in the drier eastern half of the country and is over 3000 mm yr⁻¹ in parts of the western mountains (Rohan 1986).

2.2. Data

Distribution data for the habitats was provided by the Irish National Parks and Wildlife Service (NPWS). The data are based on a combination of habitat and species distribution maps on a 10 × 10 km grid supported by NPWS surveys (NPWS 2008). These data were complemented by data for Northern Ireland Annex I reporting from the Joint Nature Conservancy Council database (JNCC 2007) (see Fig. 1a,b).

A quality-controlled set of 1961–1990 baseline climate data was used to test and construct the BEMs for the baseline period. These 10 × 10 km resolution data are derived from observed monthly climate data for 560 precipitation stations and 70 temperature stations interpolated using a polynomial regression method with an inbuilt adjustment for elevation (Sweeney & Fealy 2003).

Met Éireann (the Irish Meteorological Service) supplied HadCM3-Q16 global climate model (GCM) data dynamically downscaled to a 14 × 14 km grid resolution via the regional atmospheric model RCA3 (McGrath & Lynch 2008). The bioclimatic envelope modelling here is based on data for an A1B scenario from the above GCM and regional climate model (RCM) combination. The A1B scenario projects a rise in annual temperature of 1.3 to 1.8°C, a decrease in summer precipitation by 5 to 10% and an increase in autumn and winter precipitation by 5 to 10% by 2021–2060 relative to the 1961–1990 baseline (McGrath & Lynch 2008). The projected warming is greatest in the south and east of the country, whereas there is no clear regional trend for precipitation (McGrath & Lynch 2008). The HadCM3-Q16 simulation of winter rainfall is in the intermediate to low range among the ENSEMBLES RCMs (Jacob et al. 2008).

RCA3 simulated climate data for 1961–1990 and 2031–2060 were converted to daily and monthly mean values for temperature and precipitation variables, and R-based routines (R Development Core Team 2014) were used to re-interpolate these data to the 10 × 10 km modelling grid. The climate change signal derived with respect to the RCA3 simulated 1961–1990 baseline for each 10 × 10 km grid cell was then applied to the observed data for the variables of interest.

2.3. Derivation of explanatory variables

Both the baseline climate data and the climate change signal data were converted to monthly and seasonal values for use in the BEMs. In addition to 8 climate variables, 4 variables for topography were also included (Table 1). The data

ranges for the baseline climate variables are also provided alongside those for the A1B climate change scenario data used (Table S1 in the Supplement, available at www.int-res.com/articles/suppl/c069p177_supp.pdf). The range of candidate explanatory variables evaluated also overlap to some extent with those reported elsewhere (e.g. Marmion et al. 2009a, Engler et al. 2011, Coll et al. 2014).

Mean elevation for each 10×10 km grid cell (ArcGIS 10.2 software) was derived from a digital elevation model (GTOPO30) with a horizontal grid spacing of 30 arc s (~ 1 km), and the range was calculated as highest minus lowest elevation in the focal cell. The data were then referenced to the climatic datasets.

2.4. Modelling framework

We implemented a selection of 7 from the 9 available modelling approaches in BIOMOD in this study. The techniques included a mixture of regression methods: generalised linear models (GLMs) and generalised additive models (GAMs); the machine-learning methods artificial neural network (ANN), random forest (RF) and generalised boosting method (GBM); and 2 classification methods, classification tree analysis (CTA) and flexible discriminant analysis (FDA).

A further objective in the model building process was to screen out collinearity in the covariates selected for the baseline models. This recognises that multiple regression-based approaches can be hampered by multicollinearity among predictors (Heikkinen et al. 2006, Dormann et al. 2013). BIOMOD can usefully specify non-linear terms for GLM in particular, thereby opening up many more candidate covariate possibilities. However, there is no screen for collinearity among predictors in BIOMOD per se. Therefore, a combination of correlation matrices and principal components analysis (PCA) was used to screen the available covariates beforehand, and any collinear terms were excluded from the final covariates used. There was also *a posteriori* knowledge of where collinearity in the covariates was likely based on previous work (Coll et al. 2011, 2013, 2014).

For all 7 wet heath models, the variables used were annual temperature range, mean winter precipitation, mean winter temperature, elevation range and mean elevation. For the 7 alpine and boreal heath models, the same covariates were used, except maximum elevation replaced mean elevation. Once the variables are selected, the individual models in BIOMOD use internal measurements, based on either stepwise regression or classification error rates; the Akaike's information criterion (AIC) statistic is also evaluated internally, and the model with the lowest AIC score is chosen. BIOMOD also provides an assessment of variable importance based on the extent to which model predictions change when a given variable is randomised (Thuiller et al. 2009).

To measure changes in climatic suitability for the habitats rather than interpreting model projections as estimates of the changes in observed habitat distributions, an unlimited habitat expansion scenario was adopted, whereby the habitats are assumed to be able to track shifting suitable climate over the entire study area. We recognise that this is unrealistic for habitat modelling in particular, but the choice reflects a desire to assess the potential change in the overall climate space for the focal heath habitats in Ireland. The null or full dispersal scenarios generally considered in most studies are considered a limitation of BEMs (e.g. Thuiller et al. 2008). However, newer methods developed for mobile species (e.g. Barbet-Massin et al. 2012) are not appropriate for habitat modelling.

2.5. Model predictive performance

Projections of the probability of occurrence for each individual model were based on a threshold maximizing the true skill statistic (TSS), a commonly used threshold because it produces the most accurate predictions (Allouche et al. 2006). Model accuracy was also assessed with the area under the curve (AUC) from receiver operating characteristic plots (Fielding & Bell 1997). Although AUC has been criticised recently (e.g. Lobo et al. 2008), it still provides an informative measure of model discriminatory performance (Reineking & Schröder 2006). We also use Cohen's kappa as a further measure of model predictive performance and as a further measure widely applied in the literature.

Each individual model in BIOMOD assesses the contribution of the predictor variables to the model, and a permutation procedure enables the extraction of a measure of the relative importance of each variable. Following model calibration, a standard prediction is made; then, following randomisation of one of the variables, a new prediction is made. The correlation score between the standard and new prediction is calculated and is considered to give an estimation of the variable importance in the model (Thuiller et al. 2009).

By allowing the calculation of an ensemble prediction from all the models, the BIOMOD framework reduces the uncertainties arising from the use of only a single model. Several methods are provided to enable this, such as probability mean and weighted mean. A PCA of the median value was used and is calculated on the probabilities given by the models. This ranks the models according to their predictive performance, and in the version of BIOMOD used here, the consensus model is the model whose projection is the most closely correlated with the first axis of the PCA (Thuiller et al. 2009). It is considered to be more reliable because it is less influenced by extreme values (Thuiller et al. 2009), and a decay weighting of 1.6 was used. The decay gives the relative importance of the weights, e.g. a decay of 1 is equivalent to a committee averaging, whereby the same weights are given to all the elements.

3. RESULTS

3.1. Model performance and the importance of variables

The predicted baseline distributions obtained for all the BIOMOD wet heath models have good TSS values (0.648–0.713), kappa values (0.652–0.714) and AUC range of values (0.874–0.929) (Table 2). Similarly, the predicted baseline distributions obtained for all the BIOMOD alpine and boreal heath models have good TSS values (0.671–0.737) and good to excellent kappa values (0.670–0.738) and AUC range of values (0.858–0.936) (Table 2). This consistent performance between the models for the baseline is reflected in the mean predicted probability for each model type, which is not the case for the climate change projections, where there are substantial differences in the mean probabilities for both the wet heath (Fig. 2a) and alpine and boreal heath (Fig. 2b) models.

For the wet heath modelling, there is again consistency between the BIOMOD models in relation to the variable importance. Across the models, mean winter precipitation and mean elevation emerge as consistently important, although the relative importance of each varies between the models according to the influence of the other covariates in each individual model type (Fig. 3a). For the alpine and boreal heath models, while mean winter precipitation is also consistently the main climatic

variable of importance, there is more variation in the importance of the topographic covariates in the models. Maximum elevation emerges as the topographic variable of greatest importance in the ANN, CTA, GBM and RF models, whereas elevation range is more important in the GAM, GLM and FDA models (Fig. 3b).

3.2. Comparison of baseline and projected climate change

3.2.1. Wet heath models

A comparison of the mapped predictions for the baseline period from the 7 BIOMOD models with the observed distribution indicates that the general pattern of the spatial distribution of wet heath is well captured in all models, with incorrect predictions mainly occurring in grid cells around the Midlands (Figs. S1–S7 in the Supplement, available at www.int-res.com/suppl/c069p177_supp.pdf).

By contrast, when the A1B scenario climate change data are projected through the models, the results differ substantially between the different models. The GLM and FDA models project the greatest potential loss of climate space compared to the baseline (Table 3; Figs. S1 & S7 in the Supplement). The GAM model projects substantial losses of climate space in the south but gains in the north (Table 3; Fig. S2 in the Supplement), while the ANN and GBM models project some loss of climate space in the south with gains in the north (Table 3; Figs. S3 & S4 in the Supplement). The RF model projects considerable gains across the country (Table 3; Fig. S5 in the Supplement), with the CTA model projecting substantial fragmentation of climate space in the south and west but gains in the east and north (Table 3; Fig. S6 in the Supplement).

The BIOMOD ensemble projections indicate an overall loss of suitable climate space for wet heath, although a number of areas remain stable and some gains are also projected (Fig. 4a). Cells representing a limited expansion scenario (more realistic) and full expansion scenario (less realistic) are represented by blue squares and blue and green squares, respectively. The projected changes indicate the greatest loss of climate space to be in the south and west of the country; the most substantial losses are associated with low-elevation coastal cells and other low-elevation cells away from the mountains of the southwest and west. Overall, therefore, the models are projecting most losses of suitable climate space for low-lying southern and western cells, whereas they indicate some preservation of stable climate space for upland areas. The projected expansions of climate space are primarily in the Midlands, the east and the northeast. However, if a more realistic post hoc limited dispersal scenario is applied, whereby only gains associated with cells adjacent to the baseline distribution are counted, projected climate space gains are only realistic for 76 of the 10×10 km cells relative to the baseline.

3.2.2. Alpine and boreal heath models

A comparison of the mapped predictions for the baseline period from the 7 BIOMOD models with the observed distribution indicates that the general pattern of the spatial distribution of alpine and boreal heath is well captured in all models, with incorrect predictions mainly occurring in grid cells around the north of the country (Figs. S1–S7 in the Supplement).

By contrast, when the A1B scenario climate change data are projected through the models, the results differ substantially between the different models. The GLM

and FDA models project the greatest potential loss of climate space compared to the baseline (Table 3; Figs. S8 & S14 in the Supplement). The GAM model projects substantial losses of climate space in the south but gains in the north (Table 3; Fig. S9 in the Supplement), while the ANN and GBM models project some loss of climate space in the south with gains in the north (Table 3; Figs. S10 & S11 in the Supplement). The RF and CTA models project considerable gains across the country (Table 3; Figs. S12 & S13 in the Supplement).

The BIOMOD ensemble projection indicates a fragmentary loss of suitable climate space for alpine and boreal heath in the south and west, although many areas remain stable and regional gains are projected for the northeast (Fig. 4b). Cells representing a limited expansion scenario (more realistic) and full expansion scenario (less realistic) are represented by blue squares and blue and green squares, respectively. Overall, therefore, the models are projecting most losses of suitable climate space for low-lying southern and western cells, whereas they indicate substantial preservation of suitable climate space for upland areas. The projected expansions of climate space are primarily in the east and northeast. However, applying the more realistic post hoc limited dispersal scenario, whereby only cells adjacent to the baseline distribution are counted, projected climate space gains are only realistic for 45 of the 10×10 km cells relative to the baseline.

4. DISCUSSION

4.1. Modelling current distribution

Overall, the results here provide good climate-based models for the distribution of wet heath and alpine and boreal heath which relatively accurately replicate the observed baseline distribution of the habitats across Ireland. All of the BIOMOD models with the application of climatic-based variables are useful predictors of heath habitat distributions in Ireland. In general, macroclimate is the primary environmental control on the distribution of the heaths at the geographical scale modelled here. However, topographic variables represented in these models by elevation, through their influence on microclimate (i.e. temperature and precipitation), are also important variables.

Mean winter precipitation and elevation emerge as the key variables in all model categories, although their relative importance in relation to the other covariates varies between the model types and between the different heath habitats. For example, mean winter precipitation and mean elevation are the key variables of importance in the wet heath models, whereas elevation range and maximum elevation alongside mean winter precipitation are more important in the alpine and boreal heath models. Using elevation terms in the models supports results showing that the inclusion of topographical variables improves the predictive accuracy of models for similar habitats (Coll et al. 2011, 2013, 2014, 2016) and species of these habitats (Hodd et al. 2014) in Ireland. As climatic and topographical gradients are known to operate at different spatial scales, with the latter nested in the former (Bruun et al. 2006), the inclusion of the elevation data in this study therefore provides a more local component for all the models. Elevation range has been commonly used as a surrogate for environmental and climatic heterogeneity within grid cells in species richness modelling studies, as topographical heterogeneity compresses biotic communities into

more constricted vertical spaces (e.g. Richerson & Lum 1980, Currie 1991, Coblenz & Riitters 2004) and effectively mingles habitat types and species that are otherwise often widely spatially separated.

Precipitation and elevation (through its influence on temperature) are known key controls on the habitat distribution in the present, and their importance as covariates in the models here reflect other modelling work on the distribution of active blanket bog habitat in Ireland (Jones et al. 2006, Donnelly et al. 2008, Coll et al. 2011, 2014). Hence, the future changes in climate space projected for the habitats in response to the changes in temperature and precipitation make sense both biogeographically and topographically at the finer scale of analysis presented here for Ireland.

4.2. Modelling the effect of climate change on heath distribution

The projected reduction and re-alignment of climate space associated with the wet heath in the current study are inconsistent with suggestions that the habitat may not be sensitive to climate change. However, the work here is the first study undertaken at a finer spatial scale and with elevation terms incorporated in the BIOMOD model families. While there is a wide range of projected changes between the model families themselves, the overall model consensus is for a reduction and re-alignment of the available climate space.

Although the alpine and boreal heath models project a similarly wide range of changes in climate space between the model types, the stability of climate space as projected by the BIOMOD consensus model is more surprising. Our models indicate apparently less sensitivity for this habitat compared to the results for the wet heath, a result which is inconsistent with previous thinking, i.e. that these habitats are more sensitive to climate change than the wet heaths. Internationally important bryophyte species and communities are also considered vulnerable, while arctic–montane species are projected to see areas of suitable climate either shift northwards or contract to higher elevations (Hodd et al. 2014).

It is also surprising that the influence of the temperature terms was not more substantial in the models for both habitats. UK-based modelling, for example, indicates that combinations of temperature and precipitation variables were important in BEMs for blanket peat. For the UK, it was found that models which included measures of both hydrological conditions and maximum temperature provided a better fit to the mapped peat area than models based on hydrological variables alone (Clark et al. 2010). However, given the importance of the elevation terms in all the models, it is possible that these served as a proxy for some of the other seasonal temperature terms which could have been included. Certainly, the covariates used and the variable importance are analogous to results obtained previously using the same methods for active blanket bogs in Ireland (Coll et al. 2014). However, results here indicate that the heath habitats are potentially less sensitive than some of the other Irish habitat types modelled to date using similar methods (Coll et al. 2013, 2014).

4.3. Limitations and assumptions of the methods

The limitations and assumptions involved in using a 10×10 km grid are recognised. The important controlling variables of topographic and environmental heterogeneity, for instance, will be lost at this resolution, together with important fine-scale microclimatic controls. Similarly, for model grids at this resolution, no account

can be taken of the relative coherence or patchiness of heath habitats within individual grids where the community presence is recorded. An obvious but important point in relation to the heath communities is that projected changes in the climate space associated with the current distribution of wet heaths and alpine and boreal heaths are not the same as projecting changes in the actual distribution of the habitats over the next century. It has been suggested, for example, that wetland habitats occurring under similar conditions, even if not in a state of active growth, could well persist over decades or longer despite a reduction in climate space (Clark et al. 2010).

The BEMs presented here are based on derived statistical relationships between the known mapped distribution of heaths and climatic variables; it is unlikely that this mapped distribution represents heaths in an equilibrium state with current climate. Given historical and contemporary drivers of change, particularly grazing pressure and the use of burning, the distributions of Irish heaths are substantially modified. It is therefore possible that the calibrated baseline models do not fully capture the climate envelope reflecting sustainable conditions for the presence of heaths. Nevertheless, and despite the criticisms, BEMs and other models are providing a better understanding of the mechanisms by which species and ecosystems can be affected by climate change, and considerable improvements are being made rapidly in virtually all aspects of this emerging field (Bellard et al. 2012).

The final variables selected in the models reflect 2 primary properties of the climate (temperature and water) that are key factors affecting species and habitat distribution (e.g. Whittaker et al. 2007, Araújo et al. 2011). However, other important environmental information is omitted in the models. Therefore, the models could be refined by adding more topography and land cover variables; obvious candidates for the heath habitats would be further information on slope angle and aspect, which through their controls on light regimes influence evapotranspiration. For example, differences in light regimes between north- and south-facing aspects in temperate latitudes can produce differences in temperature equivalent to a move of ~200 km north (Austin & van Neill 2011) and lead to many differences in species composition, with, in particular, a higher diversity of bryophytes found on north-facing slopes (Hodd & Sheehy Skeffington 2011a,b). It has also been widely reported that the influence of local topography may create critical climatic refugia that are important even in studies of very large areas (e.g. Ohlemüller et al. 2008, Coll 2010, Austin & Van Neill 2011). Consequently, there is scope to incorporate more refined measures in future models which better capture the influence of topography in creating the conditions necessary for supporting heath formation. However, prior to and throughout the modelling process, we critically considered key assumptions and rigorously evaluated covariate selection based on the data available. Therefore, we consider that the results are presented in an appropriate conceptual context (*sensu* Araújo & Peterson 2012).

4.4. Implications of changing climate space for heath distributions

The projected decline and fragmentation of the climate space associated with heath habitats would have significant implications for the ecology of these complex upland ecosystems and their associated plant and animal species. Seasonal drying, for example, may affect surface microtopography and hydrology; this in turn will influence the plant composition, particularly impacting key bryophyte species (Hodd & Sheehy Skeffington 2011, Hodd et al. 2014) and habitat suitability for birds (Carroll

et al. 2011, Renwick et al. 2012) and other species. Loss of unprotected high-quality upland habitats such as heaths will result in the direct loss of upland biodiversity by physical removal of the habitats and their associated species, while degradation may cause reduced species diversity and local extinction of rare or sensitive species (Scally et al. 2010). Such a climate change-driven degradation and loss may have secondary impacts on the biodiversity value of the remaining heath areas through increased isolation and fragmentation of the remaining habitat. Additionally, upland ecosystems provide a range of ecosystem services remote from their location, e.g. the regulation of downstream areas through the flow of water; hence, any degradation or loss of these habitats has ecosystem service implications for habitats and human communities away from the uplands themselves.

Degrading heaths will also have an impact on the wider structure and function of the uplands as the overall mosaic of habitat types respond to climate change. For example, drier and warmer summers may increase the frequency, size and severity of uncontrolled fires (Albertson et al. 2010), and drought effects may become more common later in the year (e.g. Cannell et al. 2004). This may have severe impacts in areas already subject to pressures such as overgrazing, inappropriate burning, and loss of vegetation cover combined with erosion of the peat or soil. Although fire is currently not common in alpine or boreal heaths, nor recommended for management, a drier climate may result in more fires from lower altitude spreading into this habitat. This would lead to scarring of upper slopes and a slow subsequent recovery, with a likely loss of dwarf shrub cover, the moss *Racomitrium lanuginosum* and specialised montane species, to be replaced by bare ground or the rush *Juncus squarrosus* and graminoid species. There is also likely to be a modified seasonal incidence of extreme weather such as high-intensity precipitation events (Matthews et al. 2016). A substantial impact for heathlands could be a modified fire seasonality, with more summer and autumn fires than is currently the case (Albertson et al. 2010), and direct burning of the peat itself during fires, with negative consequences for the seed bank. These impacts could be exacerbated by subsequent increased winter rainfall. These factors may combine to result in increased erosion of the peaty soils associated with the wet heaths and the sparse skeletal soils associated with montane heaths.

A loss of montane and wet heath habitats in Ireland would be detrimental to the conservation of these Annex I habitats in Europe as a whole, disproportionate to the area present in Ireland. Although the alpine and boreal heath does not cover large areas in Ireland, the highly oceanic character of the habitat here means that it represents a very different aspect of this vegetation than that present across more continental mountain areas. Therefore, it is important to make every effort to conserve these habitats and to identify and mitigate against any threats to their future survival. Based on results here, climate change could be a key potential future threat to these habitats.

5. CONCLUSIONS AND IMPLICATIONS FOR FUTURE WORK

Our results indicate that the distribution of wet heath habitats in Ireland is regionally sensitive to climate change, most notably for lower-lying areas in the south and west of the country. Increasing temperature and precipitation changes may reduce and fragment the area that is suitable for heath development. This could have major implications for the lowland wet heath distributions along the western Atlantic

seaboard, where the projected losses are greatest. Offsetting these losses are climate space gains in the Midlands and the northeast and some retention of suitable climate space in upland areas in the south and west. The stability of climate space for alpine and boreal heath as projected by the BIOMOD consensus model is more surprising, as this habitat is considered more sensitive to climate change. In addition, the consensus model projects a substantial expansion of the potentially available climate space to the north and east. In summary, projected climate space losses (gains) from the BIOMOD consensus model are -40.84% (limited expansion) and -10.38% (full expansion) for wet heath and -18.31% (limited expansion) and $+28.17\%$ (full expansion) for alpine and boreal heath. However, areas which are projected to become suitable in the future would not necessarily ever be suitable for the growth of heath due to factors not included in the models, particularly geology and the presence of intensive agriculture, especially in the Midlands. These projected changes may proportionately affect both the lowland and upland heath communities, with important conservation policy implications.

Incorporating more detailed information into the BEMs can further improve confidence and reduce uncertainty in model estimates for the future distribution of Irish heaths. Specifically, information such as habitat type and species composition at a finer scale could better inform us on the status and type of heaths. Such an approach would require accurate survey data integrated at a finer spatial resolution alongside finer-meshed climate and climate change data. Other information, e.g. underlying drift, soil conditions, and slope angle and aspect, may improve model results. The distribution models presented here should be applicable to areas of wet and montane heath distribution outside Ireland, so long as data for the evaluation of the estimates are available.

Some attempt has been made to deal with uncertainty, at least in relation to differing results between the model categories, by providing the results from the individual BEMs implemented in the BIOMOD framework alongside the ensemble projection. Certainly, there is substantial variation in the results between the individual BEM types when the A1B scenario data are projected through the models. Although only the downscaled output from 1 GCM and scenario has been used to project climate space changes here, the methods lend themselves to using different GCM and RCM outputs from a range of scenarios (e.g. Fronzek et al. 2011, Garcia et al. 2012) and from different sources (e.g. Fronzek et al. 2012) to better encapsulate uncertainty. Given the importance of mean winter precipitation in all the BEM model families, if a wetter or dryer model or scenario had been used from the ENSEMBLES RCMs, the results projected via the BEMs could have varied further. Work using the new representative concentration pathways (RCPs) and multiple GCMs show that projected species distributions exhibit broad differences, depending not only on emissions scenarios but also on GCMs (Goberville et al. 2015). This is not surprising, as climate models project future climate conditions at a coarser scale of resolution than the biological and environmental data used to calibrate BEMs (Pacifci et al. 2015). Nevertheless, future work on Irish habitat modelling would benefit from using combined multi-GCM and multi-RCP data to better consider potential trajectories and uncertainties in projected future distributions.

Overall, such an expanded framework would allow the identification of adaptation strategies that are robust (i.e. insensitive) to climate change uncertainties, and would allow more confidence in identifying and targeting vulnerable areas of heath habitat for priority conservation management measures. However, future

research could integrate such a scenarios–impacts (top-down) approach alongside a vulnerability–thresholds (bottom-up) approach. Rather than trying to predict impacts through individual scenarios, such an integrated approach would help to better identify critical thresholds for climate change vulnerabilities alongside other drivers of change in these sensitive systems. Such refinements would also help inform best practice conservation management, whereby limited resources could be directed to areas coincident with healthy and functional heath communities and projected future climate suitability.

Acknowledgements. We thank the technical and scientific support staff at NPWS (Ireland) for supplying the GIS habitat maps for Irish priority habitats and species, Graham French at the National Biodiversity Network (UK) for supplying the GIS-enabled Irish Grid data and Steve Wilkinson at JNCC (UK) for the priority habitats and species database containing the Northern Ireland records. We also thank Ray McGrath and Tido Semmler at Met Éireann for providing the C4I climate change data. John Coll also thanks his ICARUS colleagues Rod Teck and Colin Holman for their input in processing the climate change data. David Bourke thanks the Royal Irish Academy for awarding a Mobility Grant which enabled his visit to Laboratoire d'Ecologie Alpine, CNRS and Université Joseph Fourier, Grenoble, France, to collaborate with Dr. Wilfried Thuiller and his team on the application of BIOMOD to undertake the climate change and biodiversity modelling. Without all of that team's goodwill, assistance and support, our progress in the methods developed here for Ireland would not have been possible. This research was supported by the Irish Environmental Protection Agency under grants 2007-CCRP-2.26 and 2010-CCRP-DS-2.3. We also very much thank the 3 anonymous reviewers who provided valuable comment and edit suggestions on the original manuscript.

FIGURES AND TABLES

Fig. 1. Current distribution of (a) wet heath and (b) alpine and boreal heath in Ireland. Blue squares denote the habitat presence; white squares denote absence. The map is based on National Parks and Wildlife Service data (Ireland) and Joint Nature Conservancy Council data (Northern Ireland)

Fig. 2. Comparison of the predictive performance of the 7 models implemented in BIOMOD illustrating the mean probability distribution shifts associated with climate change projections compared to the baseline for (a) wet heath and (b) alpine and boreal habitats. BL (blue) denotes the 1961–1990 baseline prediction for each model type; CC (red) denotes the 2031–2060 climate change projection for each model type. Error bars: SE. GLM: generalised linear model; GAM: generalised additive model; ANN: artificial neural network; GBM: generalised boosting method; RF: random forest; CTA: classification tree analysis; FDA: flexible discriminant analysis

Fig. 3. Relative importance of the variables used to model (a) wet heath and (b) alpine and boreal habitats. The variable of importance was calculated as 1 minus the correlation between the standard prediction and the prediction where the considered variable was randomised. ATR: annual temperature range; MWP: mean winter precipitation; MWT: mean winter temperature; Range: elevation range; Mean: mean elevation. ANN: artificial neural network; CTA: classification tree analysis; GAM: generalised additive model; GBM: generalised boosting method; GLM: generalised linear model; FDA: flexible discriminant analysis; RF: random forest

Fig. 4. Mapped BIOMOD consensus model outputs for (a) wet heath and (b) alpine and boreal heath habitats based on median probability ensemble forecasting method values using the true skill statistic threshold. Red squares denote projected losses of climate space for the A1B 2031–2060 scenario relative to the baseline; blue squares denote stable climate space grids (areas of suitable climate under a no dispersal — no habitat expansion — scenario); green squares denote potential climate space gains relative to the baseline; blue and green squares combined indicate areas of suitable climate under a full dispersal (habitat expansion) scenario

Table 1. Covariate selection evaluated for inclusion in the 7 bioclimatic envelope models

Name	Definition	Unit
Climate		
ATR	Annual temperature range (maximum temperature of the warmest month–minimum temperature of the coldest month)	°C
MAT	Mean annual temperature	°C
MST	Mean summer temperature	°C
MTW	Mean temperature of warmest month	°C
MWT	Mean winter temperature	°C
NAP	Net annual precipitation	mm
MSP	Mean summer precipitation (June–August)	mm
MWP	Mean winter precipitation (December–February)	mm
Topography		
Min	Minimum elevation	m
Max	Maximum elevation	m
Mean	Mean elevation	m
Range	Elevation range	m

Table 2. Summary comparison of model evaluation statistics with respect to the 7 BIOMOD modelling techniques used for wet heath and alpine and boreal habitats. TSS: true skill statistic; Kappa: Cohen’s kappa; AUC: area under the curve. GLM: generalised linear model; GAM: generalised additive model; ANN: artificial neural network; GBM: general boosting method; RF: random forest; CTA: classification tree analysis; FDA: flexible discriminant analysis

Model category	TSS	Kappa	AUC
Wet heath			
GLM	0.694	0.691	0.916
GAM	0.690	0.687	0.919
ANN	0.648	0.652	0.900
GBM	0.713	0.711	0.929
RF	0.712	0.714	0.929
CTA	0.671	0.674	0.874
FDA	0.706	0.705	0.918
CONSENSUS	0.691	0.691	0.912
Alpine and boreal heath			
GLM	0.683	0.670	0.920
GAM	0.692	0.683	0.921
ANN	0.671	0.641	0.890
GBM	0.737	0.738	0.936
RF	0.721	0.710	0.933
CTA	0.666	0.678	0.858
FDA	0.671	0.695	0.914
CONSENSUS	0.692	0.688	0.910

Table 3. Summary comparison of individual model baseline prediction calls and projected changes in climate space associated with the A1B 2031–2060 climate scenario data applied for each 10 × 10 km grid square for the wet heath habitat. GLM: generalised linear model; GAM: generalised additive model; ANN: artificial neural network; GBM: general boosting method; RF: random forest; CTA: classification tree analysis; FDA: flexible discriminant analysis. See Table 1 for acronyms

Model category	Baseline predicted presence	Baseline predicted absence	Climate change projected presence	Climate change projected absence	Projected loss	Projected stable	Projected gain	Change from baseline (%)
Wet heath								
GLM	478	485	154	809	394	499	70	−67.8
GAM	453	510	319	644	249	599	115	−29.6
ANN	522	441	525	438	154	652	157	+0.6
GBM	482	481	535	428	104	702	157	+9.0
RF	284	679	648	315	9	581	373	+56.2
CTA	504	459	510	453	178	601	184	+1.0
FDA	460	503	116	847	399	509	55	−74.8
Alpine and boreal heath								
GLM	367	596	90	873	308	624	31	−74.5
GAM	318	645	225	738	157	742	64	−29.3
ANN	384	579	334	629	95	823	45	−13.1
GBM	277	686	344	619	30	836	97	+19.5
RF	284	679	374	589	43	787	133	+24.1
CTA	244	719	333	630	10	854	99	+16.7
FDA	347	616	187	776	205	713	45	−46.2
